The triglyceride–high-density lipoprotein axis: An important target of therapy?

Philippe O. Szapary, MD, and Daniel J. Rader, MD *Philadelphia, Pa*

Coronary heart disease is the single largest cause of morbidity and mortality in the United States. The link between elevated low-density lipoprotein cholesterol (LDL-C) levels and coronary heart disease (CHD) has been clearly established. However, triglycerides (TG) are increasingly believed to be independently associated with CHD, while high-density lipoprotein cholesterol (HDL-C) is inversely associated with CHD risk. High TG and low HDL often occur together, often with normal levels of LDL-C, and can be described as abnormalities of the TG-HDL axis. This lipid abnormality is a fundamental characteristic of patients with the metabolic syndrome, a condition strongly associated with the development of both type 2 diabetes and CHD. Patients with high TG and low HDL-C should be aggressively treated with therapeutic lifestyle changes. For high-risk patients, lipid-modifying therapy that specifically addresses the TG-HDL axis should also be considered. Current pharmacologic treatment options for such patients include statins, fibrates, niacin, fish oils, and combinations thereof. Several new pharmacologic approaches to treating the TG-HDL axis are currently being investigated. More clinical trial data is needed to test the hypothesis that pharmacologic therapy targeting the TG-HDL axis reduces atherosclerosis and cardiovascular events. (Am Heart J 2004;148:211–21.)

Coronary heart disease (CHD) is the single largest cause of morbidity and mortality in the United States. The link between elevated cholesterol and CHD has been clearly established, and clinical trials have found that a 1% reduction in serum total cholesterol (TC) reduces CHD risk by 2%. The National Cholesterol Education Program (NCEP) clinical guidelines for the treatment of hypercholesterolemia in adults identify low-density lipoprotein cholesterol (LDLC) as the primary treatment target.[1] Risk assessment limited to LDL-C, however, fails to capture a significant portion of patients at risk for CHD, and patients effectively treated for elevated LDL-C still experience a significant number of coronary events. Thus increasing attention is being focused on other lipoprotein fractions, such as high-density lipoprotein cholesterol (HDL-C) and triglycerides (TG), as additional potential targets of therapy. Elevated serum TG combined with low HDL-C, a condition often associated with smaller, dense LDL particles, is frequently referred to as atherogenic dyslipidemia or the "lipid triad" and is most often seen in the context of the metabolic syndrome. This syndrome represents a cluster of metabolic abnormalities driven by abdominal obesity and insulin resistance, leading to the development of high blood pressure, elevated TG, and depressed HDL-C levels as well as impairments of glucose tolerance.[1] The accumulating evidence suggests that metabolic syndrome is strongly associated with the development of type 2 diabetes and clinical CHD.[2] Since lipoprotein particle size is not routinely obtained in clinical practice, and since elevated TG and depressed HDL-C can occur together, we refer to this dyslipidemia as an abnormality of the TG-HDL axis. Because abnormalities of the TG-HDL often occur in the setting of a "normal" LDL-C, new approaches, not covered in detail in the recent NCEP guidelines, need to be developed in addressing this dyslipidemia. In this review, we focus on the epidemiology and treatment of disorders of the TG-HDL axis, and provide a clinical framework to address this increasingly common dyslipidemia.

Elevated TG and low HDL-C levels as CHD risk factors

There is little doubt that decreased HDL-C is a potent risk factor for CHD, independent of other known risk factors. In fact, both observational studies and controlled clinical trials suggest that each 1% increase in HDL-C is associated with a 2% to 3% reduction in risk of CHD.[3] However, there is more debate as to the independent association of TG levels with CHD risk. Although some epidemiologic studies have not found a consistent association of TG level with CHD mortality,[4] the bulk of the evidence now suggests that elevated fasting TG level is in fact an independent risk factor for CHD. For example, the Copenhagen Male Study, which followed 2906 white men over 8 years, found that fasting serum TG in the upper 2 tertiles was independently associated with incidence of CHD.[5] In this cohort, middle-aged white men with fasting TG ≥142 mg/dL had an adjusted risk ratio for CHD of 2.2 (1.4–

All of the national and transnational screening and therapeutic guidelines are based on total or LDL cholesterol.

This presumes that cholesterol is the most important lipoprotein-related proatherogenic risk variable.

On the contrary, risk appears to be more directly related to the number of circulating atherogenic particles that contact and enter the arterial wall than to the measured concentration of cholesterol in these lipoprotein fractions.

Each of the atherogenic lipoprotein particles contains a single molecule of apolipoprotein (apo) B and therefore the concentration of apo B provides a direct measure of the number of circulating atherogenic lipoproteins.

Evidence from fundamental, epidemiological and clinical trial studies indicates that apo B is superior to any of the cholesterol indices to recognize those at increased risk of vascular disease and to judge the adequacy of lipid-lowering therapy.

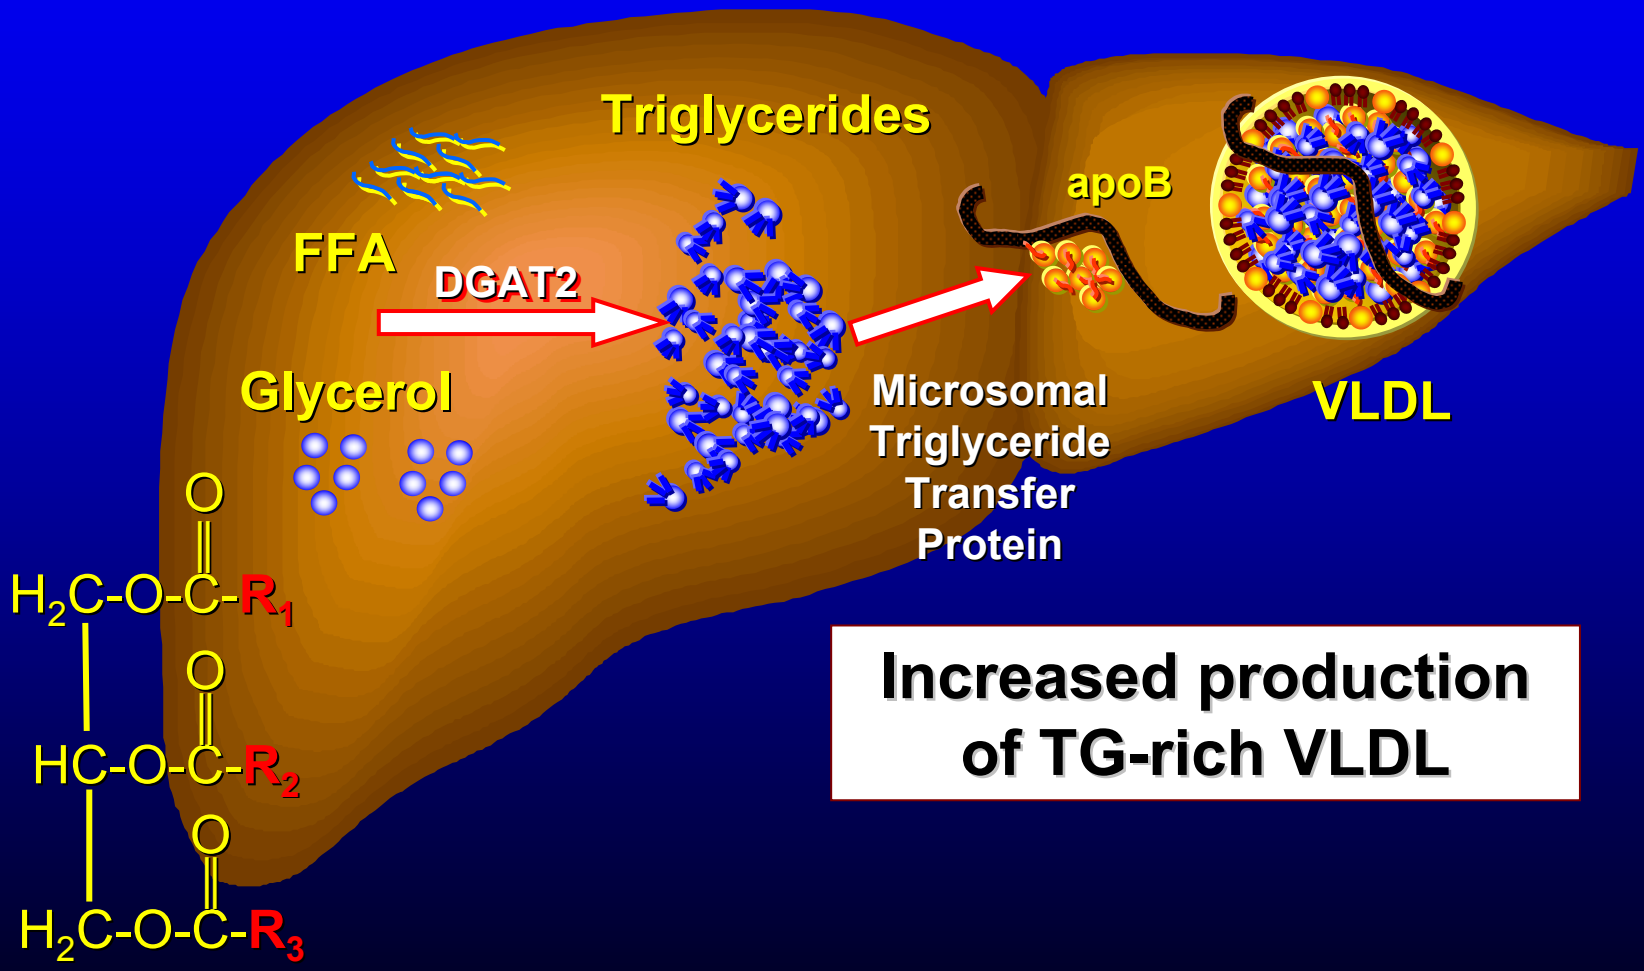
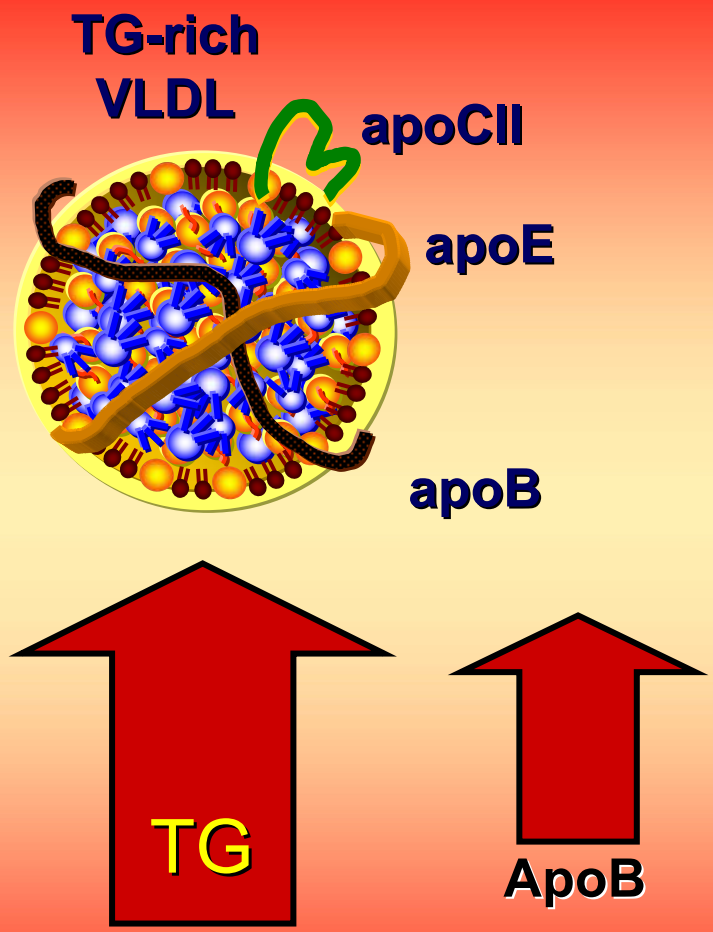
Understanding Triglycerides

↑ VLDL Synthesis in Diabetics



Increased production of TG-rich VLDL

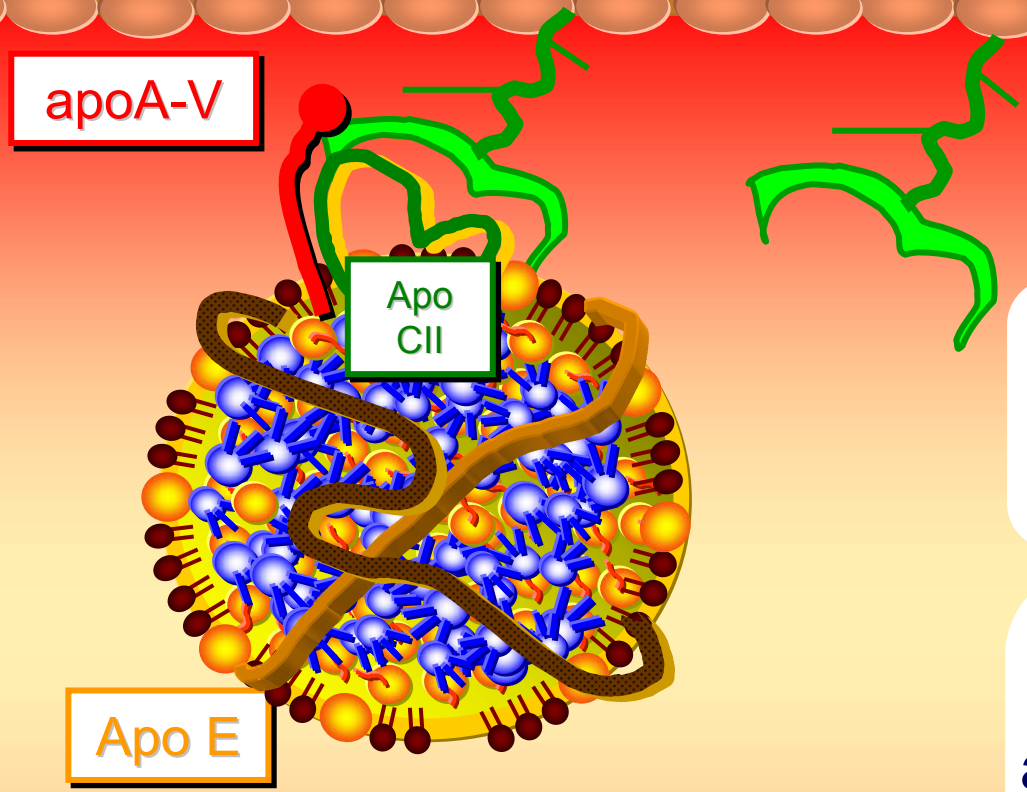
Lipoprotein Abnormalities in TG/HDL Axis Disorders



- Increased hepatic production of large apoB enwrapped TG-rich VLDL particles
- The more VLDL that is produced, the higher the apoB will be

Triglyceride Cholesteryl ester

ApoAV and TG-rich VLDL Lipolysis



Lipoprotein Lipase (LPL)

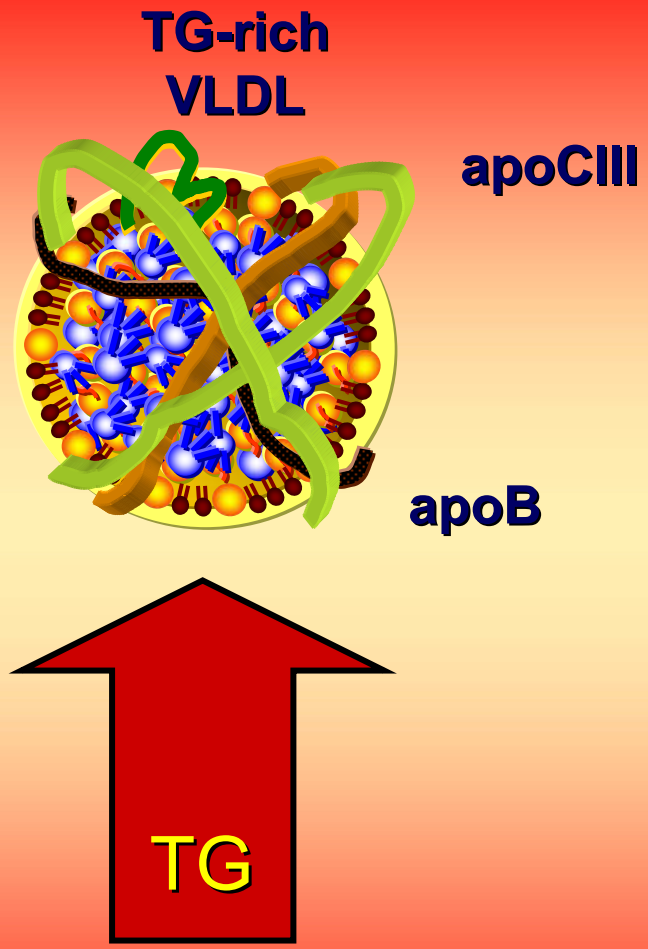
ApoA-V targets VLDL to proteoglycans placing VLDL in close proximity to LPL

After hydrolysis, VLDL remnants are released and apoA-V can be transferred to HDL and reused.

AV deficiency leads to hypertriglyceridemia

Merkel M et al. JCI 2006;115:2694-6

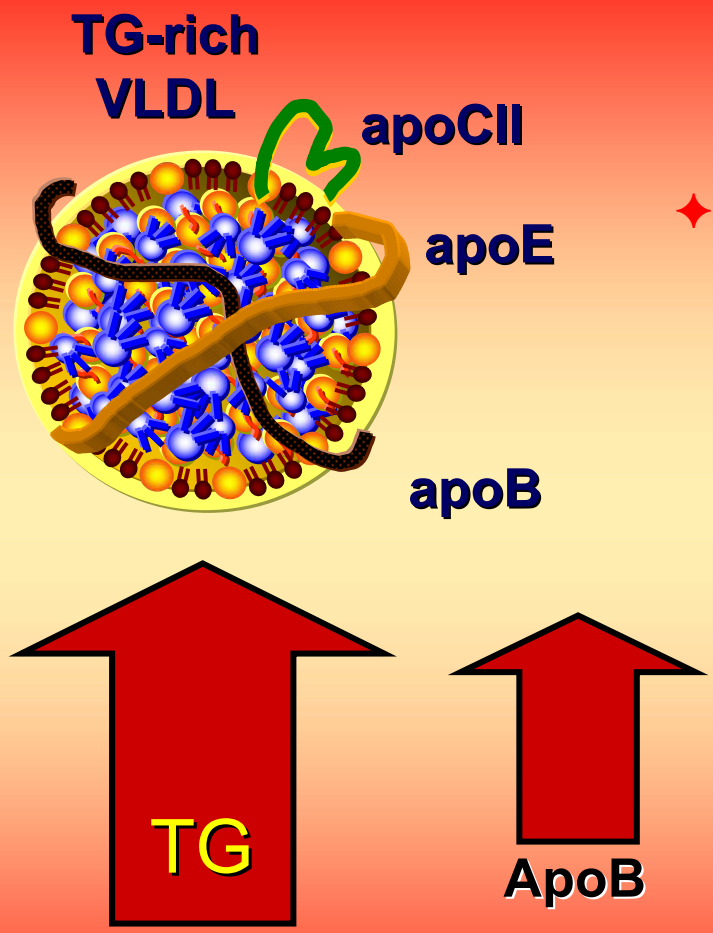
Lipoprotein Abnormalities in TG/HDL Axis Disorders



- ↑apoCIII is an independent risk factor for CHD
- ↑ apoCIII blocks or displaces apoCII and apoE, which delays VLDL lipolysis
- ↑apoCIII is associated with fasting and postprandial hypertriglyceridemia
- ↑apoCIII is common in insulin resistant patients

Triglyceride Cholesteryl ester

Rheological Abnormalities in TG/HDL Axis Disorders



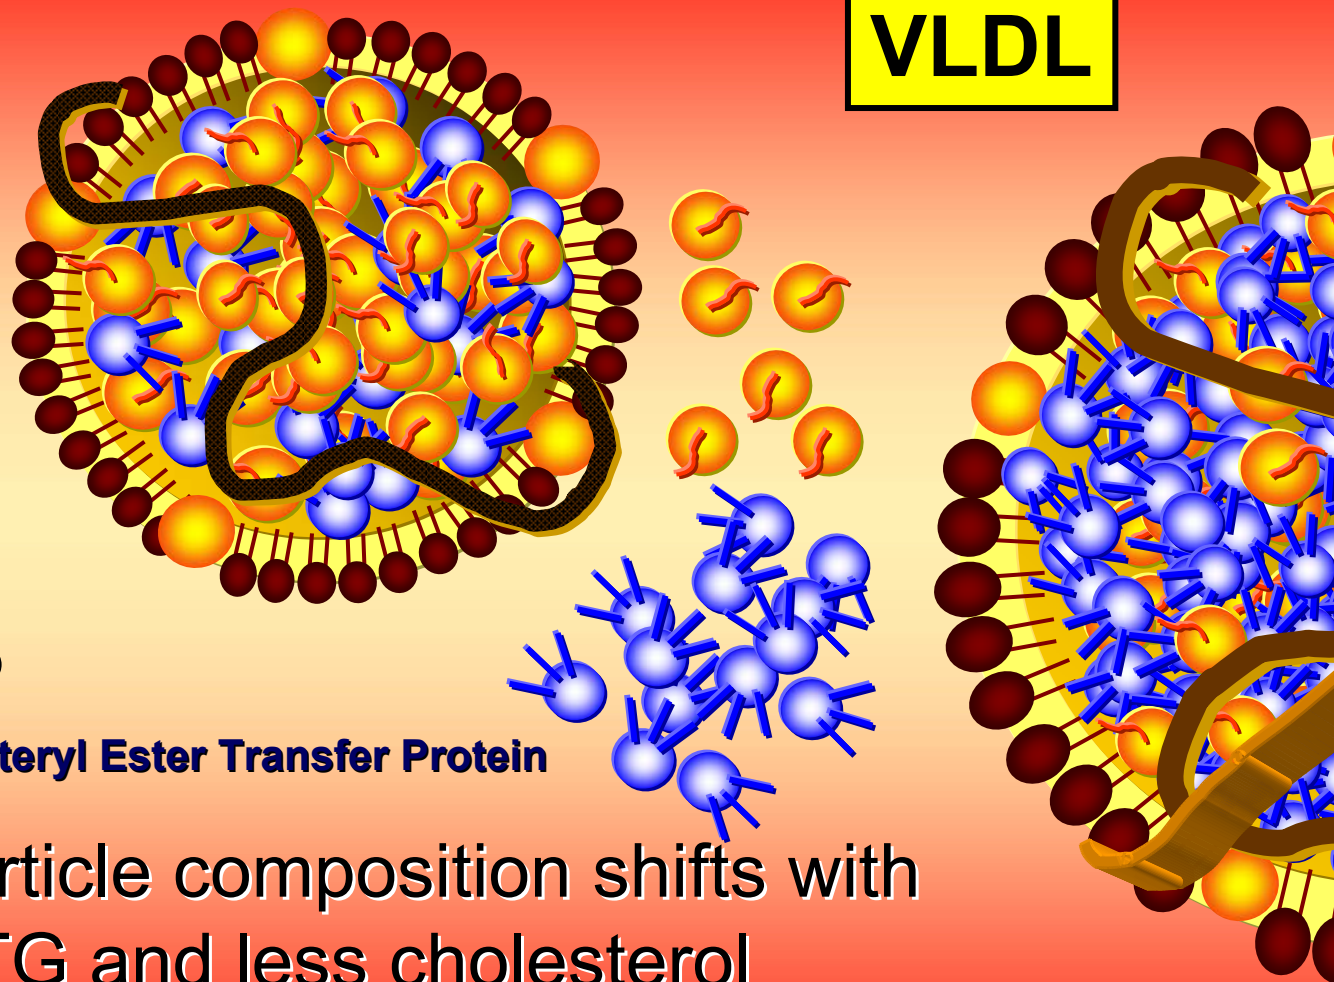
- **Increased hepatic production of large TG-rich VLDL particles is also associated with**
  - **Increased blood viscosity**
  - **Decreased arterial flow-mediated dilation (endothelial dysfunction)**
  - **Increased hypercoagulability**

Triglyceride Cholesteryl ester

LDL Particles in Patients with Elevated TG

LDL

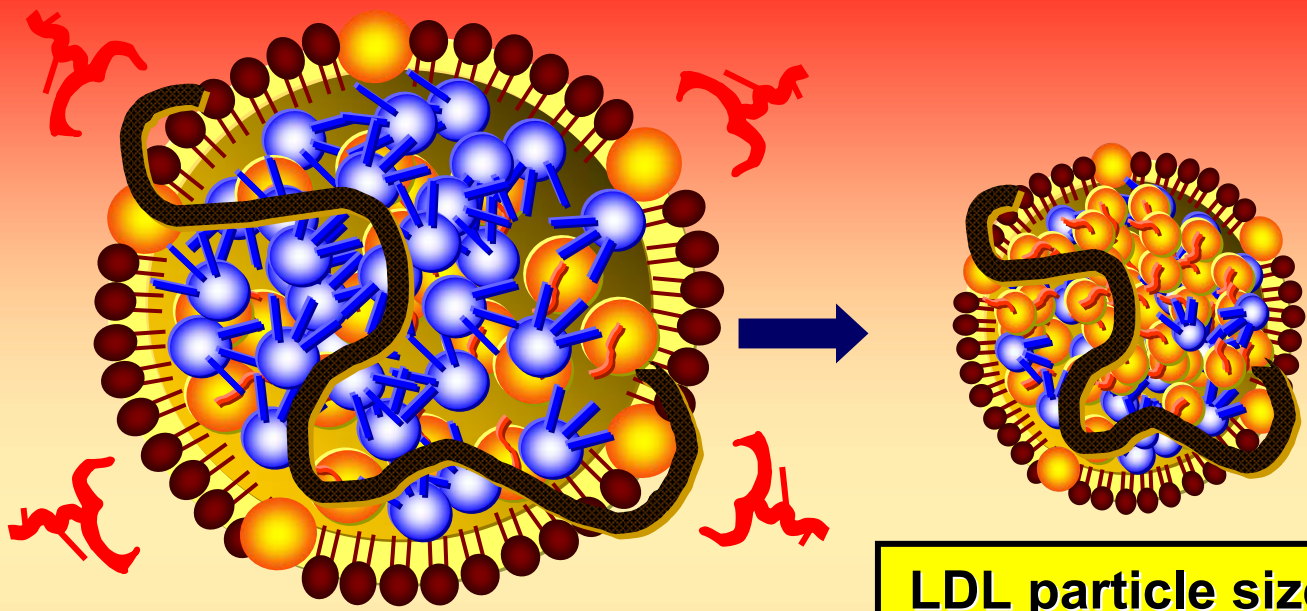
LDL-C is reduced



The LDL particle composition shifts with more TG and less cholesterol

Fate of TG-rich LDL Particles

LDL–C is reduced

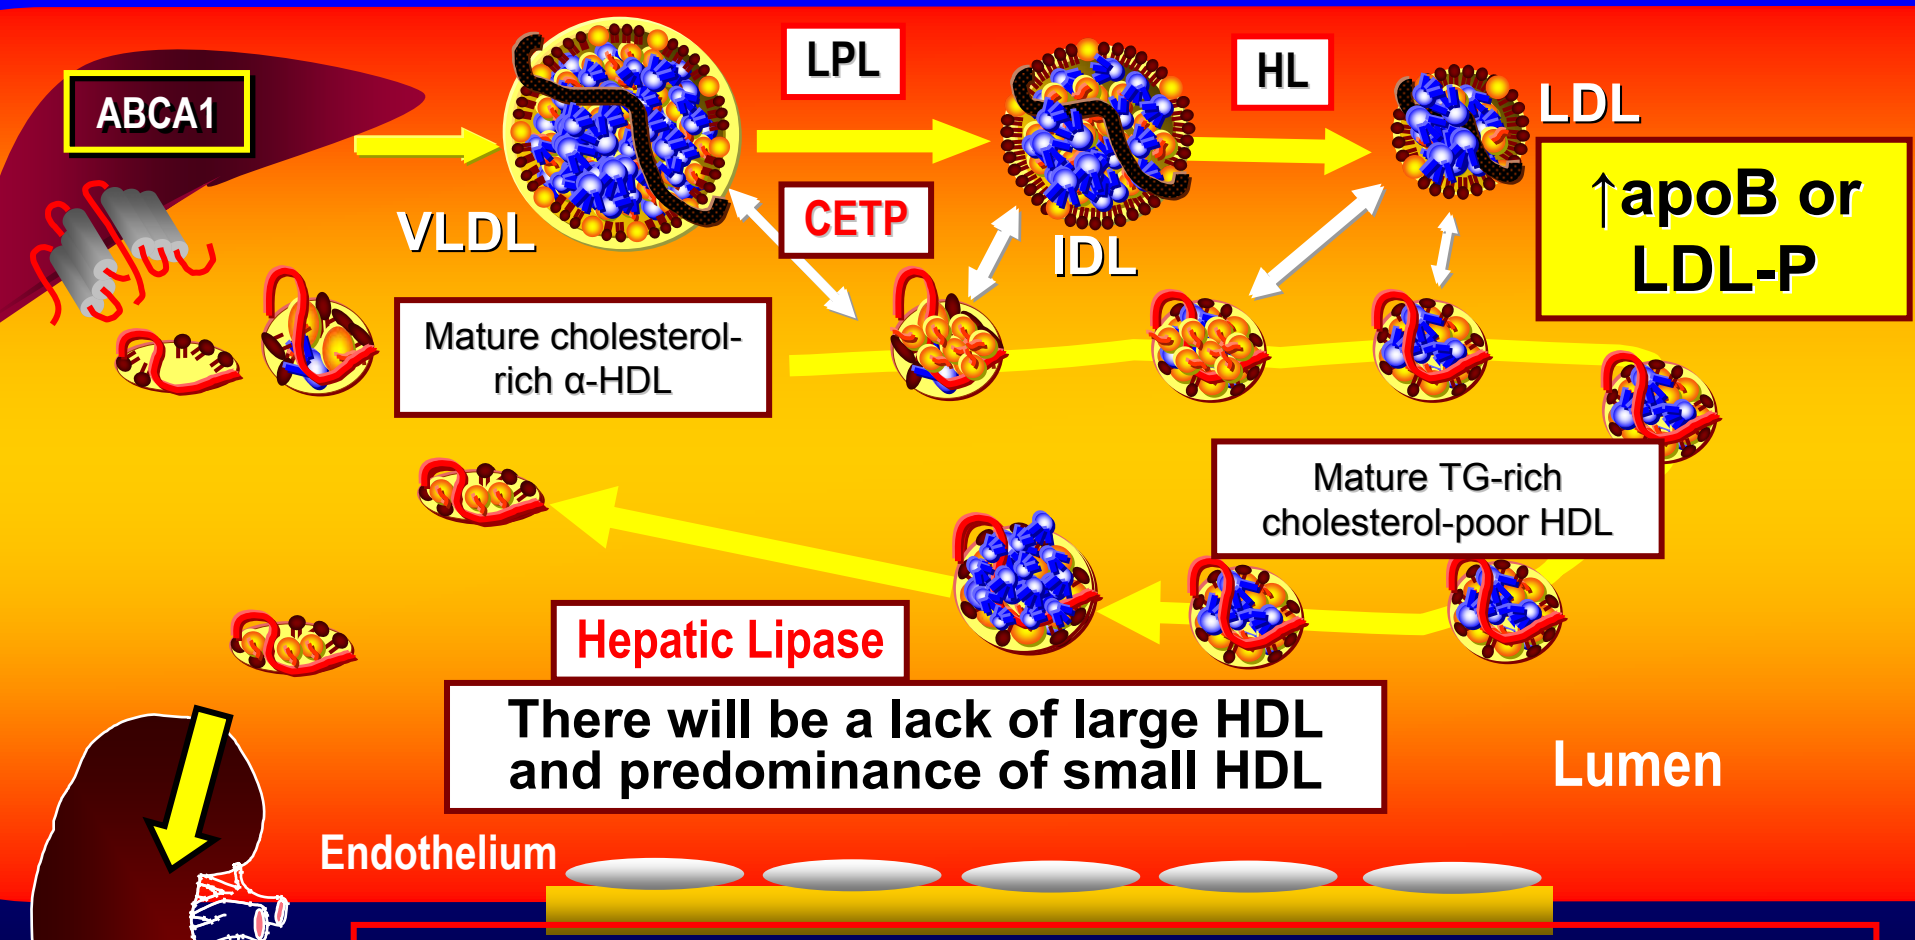


↑ LDL-P

LDL particle size is reduced

Hepatic Lipase causes further lipolysis (hydrolysis of TG & phospholipids) which reduces the size of the LDL particle

Triglyceride HDL Axis



HDL_3, facilitated by CETP, gathers TG, becomes a larger, TG rich HDL_2 which is subject to lipolytic action of hepatic lipase

With TG removal the large HDL_2 becomes a small HDL_3 which is is then subject to renal elimination or relipidation at ABCA1

Use of Fibrates

One class of drugs that modestly raises HDL-C is the fibrates.

Post-hoc analysis of several clinical trials with fibrates indicates that they reduce risk for CHD events in patients with high triglycerides and low HDL-C, especially when the patients have diabetes or characteristics of the metabolic syndrome.

Although the evidence base to support fibrate therapy is not as strong as that for statins, fibrates may have an adjunctive role in the treatment of patients with high triglycerides/low HDL-C,

especially in combination with statins.

Mortality and Fibrates

- Worldwide clinical experience with various fibrates is vast
- No evidence of specific toxicity that enhances non-CHD mortality has emerged
- This experience, taken in the light of all the clinical trials, provides little support for the concern that fibrates carry significant short-term toxicity that precludes their use for appropriately selected persons.

Use of Niacin

Another drug that raises HDL-C is **nicotinic acid**. Several clinical trials support the efficacy of nicotinic acid for reduction of CHD risk, both when used alone and in combination with statins.

The combination of a statin with nicotinic acid produces a marked reduction of LDL-C and a striking rise in HDL-C. statin/nicotinic acid combination.

Although the majority of patients can tolerate nicotinic acid therapy, a sizable minority are intolerant because of a variety of side effects.

Targeting HDL Metabolism and RCT

HDL metabolism is exceedingly complex, and because the protective ability of HDL may relate to the flux of cholesterol through the RCT pathway and to other aspects of HDL functionality, the plasma level of HDL-C alone **is almost certainly not** an adequate predictor of the potential clinical benefit of an HDL-targeted therapy.

Some interventions that raise HDL-C may not reduce atherosclerosis or cardiovascular events; conversely, other interventions may not raise HDL-C but through effects on RCT or HDL function may have major effects on atherosclerosis or cardiovascular events.

There is a great need for the development of novel biomarkers and kinetic methods to assess the effects of novel interventions on RCT and HDL function.

Duffy D & Rader D. Circulation 2006;113:1140-1150
